Abstract

A modification of Grover's algorithm is proposed, which can be used directly as a fast database search. An explicit two q-bit example is displayed in detail. We discuss the case where the database has multiple entries corresponding to the same target value.

In the usual application of Grover's algorithm [1, 2], one envisages an "oracle", T , into which one inputs an integer I and which returns the value $T(I) = 0$ for all values of I except $I = I_0$ for which $T(I_0) = 1$. A practical application of this algorithm (if it could be realised experimentally for very large integers) could be a fast search of a database. In other words given a function $f(I)$ which maps the integers I into the integers F , but which cannot be easily inverted, the algorithm could be used to find for which value of the input integer I , the function $f(I)$ was equal to F . In order to use the algorithm for this purpose it is necessary to consider the interaction of the "database" with the oracle, T , which is likely to be very involved.

In this note we propose a minor modification of Grover's algorithm which can be used directly for such database searches. To begin with we will assume that the function is one-to-one and onto. We will discuss the consequences of removing this restriction later.

We suppose that the argument I is stored in an L q-bit control register in the state $|I\rangle$ and the value $F = f(I)$ is stored in an L q-bit target register in the state $|F\rangle$. We

consider a device U_f which encodes the function $f(I)$ such that the action of the device may be represented by the unitary operator $\hat{U}_f$ where

$$\hat{U}_f |I\rangle \otimes |K\rangle = |I\rangle \otimes |K \oplus f(I)\rangle. \quad (1)$$

The device U_f is reversible which means that the operator $\hat{U}_f$ is idempotent. In particular

$$\hat{U}_f |I\rangle \otimes |0\rangle = |I\rangle \otimes |f(I)\rangle. \quad (2)$$

$$\hat{U}_f |I\rangle \otimes |f(I)\rangle = |I\rangle \otimes |0\rangle. \quad (3)$$

Other devices which we shall need are a Hadamard gate, $H^{(c)}$, [3] acting on the control register whose actions on each q-bit in that register may be represented by the matrix

$$\frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix},$$

and the operators $S_I^{(c)}$ ($S_F^{(t)}$) which rotate the phase of the state by π if the control (target) register is in the state $|I\rangle$ ($|F\rangle$), but leaves all other states unaltered.

Such a device could be realized in practice by the addition of an extra q-bit for each register, called the auxiliary q-bit. Thus, for example, for the device $S_{F_0}^{(t)}$, the target register could be spin- $\frac{1}{2}$ particles at L different sites in a molecule or polymer and the auxiliary q-bit could be a further spin- $\frac{1}{2}$ particle located at a different site. The auxiliary bit is sufficiently close to the q-bits of the target register so that the spin-spin interactions are non-negligible, but distinct owing to the different separations between the q-bits of the target register and the auxiliary q-bit. On the other hand the spin- $\frac{1}{2}$ particles representing the control register would have to be sufficiently far from this auxiliary q-bit for spin-spin interactions between the control register q-bits and the auxiliary q-bit to be negligible.¹ Now if the magnetic moment of the auxiliary q-bit is μ and a static magnetic field of magnitude B is applied in the z -direction, then the Hamiltonian of the auxiliary q-bit when it is in the state $|i\rangle$, is

$$H_{aux} = \mu B \left(i - \frac{1}{2} \right) + \sum_{l=1}^L \lambda_l (-1)^{(i+f_l)}, \quad (4)$$

where λ_l is proportional to the interaction between the auxiliary q-bit and the l^{th} q-bit of the target register, which is in the state $|F\rangle$ where f_l is the l^{th} bit of F , i.e.

$$F = \sum_{l=1}^L f_l 2^{(l-1)}.$$

The resonant frequency for spin flip of the auxiliary bit depends on F and may be written

$$\omega_{res}(F) = \mu B - \sum_{l=1}^L \lambda_l (-1)^{f_l}, \quad (5)$$

¹It will, however, be necessary for the control register q-bits and the target register q-bits to be sufficiently close to each other so that the spin-spin interactions between them may be employed in order to construct the device U_f .

A 180° pulse of RF magnetic field with frequency $\omega_{res}(F_0)$ in the y -direction will flip the spin of the auxiliary q-bit if and only if the target register is in the state $|F_0\rangle$. If we initialise the auxiliary q-bit in the state

$$\frac{1}{\sqrt{2}}(|0\rangle - |1\rangle),$$

this will introduce a minus sign if and only if the target register is in the state $|F_0\rangle$. The device $S_I^{(c)}$ can be constructed in a similar manner.

We suppose that we wish to search for the (unknown) value I_0 for which $f(I_0)$ is equal to the known value F_0 . It is convenient to work in the two dimensional subspace of states defined by

1. The state we wish to project out

$$|\Phi_1\rangle \equiv |I_0\rangle \otimes |F_0\rangle \quad (6)$$

2. An orthogonal state consisting of a superposition of all the other states with equal coefficients

$$|\Phi_2\rangle \equiv \frac{1}{\sqrt{2^L - 1}} \sum_{I \neq I_0} |I\rangle \otimes |f(I)\rangle. \quad (7)$$

The system is initialised by acting on the state $|0\rangle \otimes |0\rangle$ with the Hadamard gate on the control register followed by the device U_f . This produces the state

$$|\Psi_1\rangle = \hat{U}_f \hat{H}^{(c)} |0\rangle \otimes |0\rangle = \cos \beta |\Phi_1\rangle + \sin \beta |\Phi_2\rangle, \quad (8)$$

where

$$\sin \beta = \frac{1}{\sqrt{2^L}}.$$

Now we consider the combination of operations, $S_{F_0}^{(t)}$, followed by U_f , followed by $H^{(c)}$ followed by $S_0^{(c)}$ followed by $H^{(c)}$ followed by U_f . A little algebra shows that in the two-dimensional subspace under consideration the operator $\hat{O}$ corresponding to this combination of operations,

$$\hat{O} \equiv \hat{U}_f \hat{H}^{(c)} \hat{S}_0^{(c)} \hat{H}^{(c)} \hat{U}_f \hat{S}_{F_0}^{(t)},$$

may be written as the 2×2 matrix, [4, 5]

$$\hat{O} = - \begin{pmatrix} \cos 2\beta & \sin 2\beta \\ -\sin 2\beta & \cos 2\beta \end{pmatrix}. \quad (9)$$

This is most readily seen by observing that the operator $\hat{S}_0^{(c)}$ (acting on the control register) may be written

$$\hat{S}_0^{(c)} = I - 2|0\rangle\langle 0|, \quad (10)$$

(I is the identity), whereas the operator $\hat{S}_{F_0}^{(t)}$ (acting on the target register) may be written

$$\hat{S}_{F_0}^{(t)} = I - 2|F_0\rangle\langle F_0|. \quad (11)$$

Together with the matrix elements

$$\langle \Phi_1 | \hat{U}_f \hat{H}^{(c)} | 0 \rangle \otimes | 0 \rangle = \sin \beta \quad (12)$$

$$\langle \Phi_2 | \hat{U}_f \hat{H}^{(c)} | 0 \rangle \otimes | 0 \rangle = \cos \beta, \quad (13)$$

the result (9) follows.

Thus we see that the application of the operator $\hat{O}$ N times where N is the nearest integer to the quantity ν where

$$\nu = \frac{\pi}{4 \sin^{-1} \left(\frac{1}{\sqrt{2^L}} \right)} - \frac{1}{2} \quad (14)$$

on the initial state $|\Psi_1\rangle$ will project the system into a state which is almost pure $|\Phi_1\rangle$. A measurement of the control register will now return the value I_0 . At the same time one should measure the state of the target register as a check. Errors can occur owing to the fact that there is still some probability (of order $1/2^L$) for the system to be in the unwanted state $|\Phi_2\rangle$. These errors are, of course, amplified by decoherence effects. However, the error rate should still be small compared with unity so that any error is very unlikely to survive a repetition of the experiment.

As a pedagogical exercise we now consider a simple example in which the control and target registers each consist of two q-bits. Note that if we set $L = 2$ in eq.(14) we find exactly $\nu = 1$, which means that the system should be in the required state after a single pass through the combination of devices. The standard Grover's algorithm for two q-bits has been achieved using NMR [6, 7] and this is currently being extended to three q-bits, so perhaps the example considered here presents the next experimental challenge. We will take the example of the function

$$f(I) = (3 - I), \quad (I = 1, \dots, 3), \quad (15)$$

and pretending that we are unable to invert this function we search for the value of I for which $f(I) = 2$.

For two q-bit registers the devices required are represented by operators which can be written in terms of 2×2 matrices. For the operators acting on the control register we have

$$\hat{H}^{(c)} = \frac{1}{2} \begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & -1 & 1 & -1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 \end{pmatrix} \quad (16)$$

$$\hat{S}_0^{(c)} = \begin{pmatrix} -1 & & & \\ & 1 & & \\ & & 1 & \\ & & & 1 \end{pmatrix}. \quad (17)$$

The operator acting on the target register is given by

$$\hat{S}_2^{(t)} = \begin{pmatrix} 1 & & & \\ & 1 & & \\ & & -1 & \\ & & & 1 \end{pmatrix}, \quad (18)$$

and the operator $\hat{U}_f$ acts on both registers. We shall not write this out explicitly. The only action that we need is

$$\hat{U}_f |I\rangle \otimes |0\rangle = |I\rangle \otimes |3 - I\rangle. \quad (19)$$

Now we follow through the algorithm step by step.

1. Pass the system in the state $|0\rangle \otimes |0\rangle$ through a Hademard gate on the control register to obtain

$$|\Psi_0\rangle = \hat{H}^{(c)} |0\rangle \otimes |0\rangle = \frac{1}{2} (|0\rangle \otimes |0\rangle + |1\rangle \otimes |0\rangle + |2\rangle \otimes |0\rangle + |3\rangle \otimes |0\rangle). \quad (20)$$

2. Pass the system in the state $|\Psi_0\rangle$ through the device U_f to obtain

$$|\Psi_1\rangle = \hat{U}_f |\Psi_0\rangle = \frac{1}{2} (|0\rangle \otimes |3\rangle + |1\rangle \otimes |2\rangle + |2\rangle \otimes |1\rangle + |3\rangle \otimes |0\rangle). \quad (21)$$

3. Pass the system in the state $|\Psi_1\rangle$ through the device $S_2^{(t)}$ to obtain

$$|\Psi_2\rangle = \hat{S}_2^{(t)} |\Psi_1\rangle = \frac{1}{2} (|0\rangle \otimes |3\rangle - |1\rangle \otimes |2\rangle + |2\rangle \otimes |1\rangle + |3\rangle \otimes |0\rangle). \quad (22)$$

4. Pass the system in the state $|\Psi_2\rangle$ through the device U_f to obtain

$$|\Psi_3\rangle = \hat{U}_f |\Psi_2\rangle = \frac{1}{2} (|0\rangle \otimes |0\rangle - |1\rangle \otimes |0\rangle + |2\rangle \otimes |0\rangle + |3\rangle \otimes |0\rangle). \quad (23)$$

5. Pass the system in the state $|\Psi_3\rangle$ through the Hademard gate acting on the control register to obtain

$$|\Psi_4\rangle = \hat{H}^{(c)} |\Psi_3\rangle = \frac{1}{2} (|0\rangle \otimes |0\rangle + |1\rangle \otimes |0\rangle - |2\rangle \otimes |0\rangle + |3\rangle \otimes |0\rangle). \quad (24)$$

6. Pass the system in the state $|\Psi_4\rangle$ through the device $S_0^{(c)}$ to obtain

$$|\Psi_5\rangle = \hat{S}_0^{(c)} |\Psi_4\rangle = \frac{1}{2} (-|0\rangle \otimes |0\rangle + |1\rangle \otimes |0\rangle - |2\rangle \otimes |0\rangle + |3\rangle \otimes |0\rangle). \quad (25)$$

7. Pass the system in the state $|\Psi_5\rangle$ through the Hademard gate acting on the control register to obtain

$$|\Psi_6\rangle = \hat{H}^{(c)} |\Psi_5\rangle = -|1\rangle \otimes |0\rangle. \quad (26)$$

8. Finally we pass the system in the state $|\Psi_6\rangle$ through the device U_f to obtain the required result

$$|\Psi_7\rangle = \hat{U}_f|\Psi_6\rangle = -|1\rangle \otimes |2\rangle \quad (= -|\Phi_1\rangle). \quad (27)$$

Here we see role played by the modification to Grover's original method, namely the interposition of the device U_f before the application of the Hademard gate for the first time. This clears the target register and without it the penultimate step (7) would not have led to the pure state $|\Psi_6\rangle$. A further application of U_f is necessary before the process can be iterated.

We end by discussing the situation where the function $f(I)$ is not one-to-one or onto. Firstly suppose that the target register is larger than the control register and we accidentally search for a value of F_0 to which there is no corresponding I_0 such that $f(I_0) = F_0$. In this case the operator $\hat{S}_{F_0}^{(t)}$ becomes effectively the identity operator and the effect of the product $\hat{O}$ of operators is just to flip the overall sign. In this case the resulting measurement of the control register after N of these operations will simply return any one of the values of I with equal probability and there will, of course, be an error when the target register is measured, which will persist through subsequent repetitions.

On the other hand if the function is not one-to-one then one may adapt the generalization proposed in refs.[4, 8, 9]. If there are g values of I , namely I_0^r , $r = 1 \cdots g$, for which $f(I_0^r) = F_0$, then the number of applications of the operator $\hat{O}$ required to produce the required result becomes the nearest integer to $\nu(g)$ where

$$\nu(g) = \frac{\pi}{4 \sin^{-1}\left(\sqrt{\frac{g}{2L}}\right)} - \frac{1}{2}. \quad (28)$$

This projects out the state

$$|\Phi_1\rangle = \frac{1}{\sqrt{g}} \sum_{r=1}^g |I_0^r\rangle \otimes |F_0\rangle, \quad (29)$$

so that a measurement of the control register will yield one of the values of I_0^r with equal probability. If the degeneracy, g is unknown then the method proposed in ref.[4] can also be used here.
